Abstract: The analysis and design of reinforced concrete members (such as beams, columns, and shear walls) is fundamental to civil and structural engineering. Classical design methods based on hand calculations or interaction diagrams are available for various reinforced concrete sections. The goal of this study is to develop a new alternative design method for reinforced concrete shear walls using mathematical programming and numerical optimization. The design of reinforced concrete shear walls is based on the latest American Concrete Institute ACI 318-19 Code. The design method relies on an optimization formulation to determine the minimum required steel area subject to given factored loads (such as a combined bending moment and axial force on a concrete section). This study intends to present the design of concrete shear wall sections in a rigorously derived framework using different formulations. To make it more practical for civil and structural engineers to use, a widely available numerical solver in a Microsoft Excel spreadsheet is adopted as the optimization engine. Concrete shear wall examples are analyzed and designed using the proposed method, and the results are compared with those obtained using classical design methods. The new method using numerical optimization works well and is easy to implement in an Excel spreadsheet. The proposed design method provides a useful alternative for practical engineering applications.

Keywords: reinforced concrete; shear walls; mathematical programming; numerical optimization; ACI 318

1. Introduction

Design optimization of reinforced concrete structures has been investigated for many years [1,2]. The purpose of this research was to employ optimization methods in order to create practical and easily employed methods to solve reinforced concrete analysis and design problems. Ordinary reinforced concrete design is a tedious and iterative process in which multiple methods can be employed to approach a problem. Certain solutions can take many design iterations to reach and are often overly conservative. Using optimization methods and the Microsoft Excel solver for practicality and ease of use, the ordinary shear wall was designed with the goal of minimizing the total steel area in the shear wall for given loading criteria. This was employed as concrete shear walls are often conservatively designed as columns using interaction diagrams and the amount of steel used may be overconservative. The method involved the use of a thin continuous plate of steel over the length of the shear wall in place of individual bars. The plate was then discretized into smaller elements with each element representing a small area of the total steel area. Using the Excel solver, the program determined the smallest allowable total steel area based on the given loading criteria and shear wall dimensions.

2. Ordinary Shear Wall Design Using Optimization and Element Method

2.1. Optimization Formulation

The design objective was to minimize the total steel area in a shear wall, as:

$$C(A_s) = A_s \quad (1)$$

To analyze the required vertical steel area, the steel was modeled as a continuous plate and broken up into individual elements, with each element representing a portion of the total steel area. Multiple iterations were run in which the number of elements was varied to achieve convergence and verify the results for the required steel area. The Excel solver was used and equations for moment equilibrium, axial load equilibrium, and concrete analysis (Appendix A) were programmed to determine the optimized area of steel per element and hence the optimized total area of steel. The equilibrium equations were treated as equality constraints in numerical optimization.

2.2. Element Analysis and Design Theory

The element method consisted of splitting the steel plate into individual elements, with each element having its own length based on the number of elements “n” (Equations (2) and (3)). The depth “d” used for the moment capacity of the shear wall was taken at the middle of each element with the assumption that all the steel area was centered in the middle of the element (Equations (4) and (5)). The total steel area was split equally amongst all the elements based on the number of elements “n” used. Figure 1 shows the concept of how the steel plate was divided into elements and how the area and depth were found.

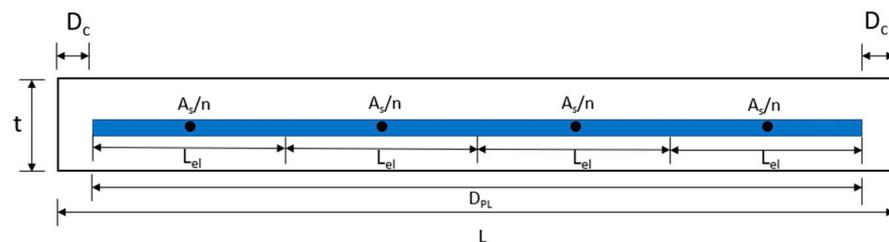

Figure 1. Concept of the element design method.

Using this method allowed for the elements to act as individual bars with their own required steel area based on the given loading criteria and for the depth and number of elements to be varied based on user input. In order to determine the total steel area required, the total steel area was input as a variable that the solver determined based on the loading and dimension of the wall.

Length of continuous steel plate:

$$d_{pl} = L - 2 \times (\text{Concrete Cover}) \quad (2)$$

In Equation (2), the length of the continuous plate is found using the length of the wall “L” and subtracting the on-center concrete cover on each side.

Length of each steel element:

$$L_{el} = d_{pl}/n \quad (3)$$

In Equation (3), the length of each element is found by taking the length of the plate “ d_{pl} ” and dividing it by the number of elements “n”, which are determined by user input.

Individual steel area of each element:

$$A_{s_{el}} = A_s/n \quad (4)$$

In Equation (4), the area of the steel per element is found by taking the total steel area “ A_s ” and dividing by the number of elements “n”.

Depth of each steel element:

$$d_{el} = \text{Concrete Cover} + (n_i - 0.5) \times L_{el} \quad (5)$$

The depth of elements “ d_{el} ” used for the analysis of the moment capacity for each steel element was found by taking the concrete cover and the length of each element “ L_{el} ” and multiplying by the number of the individual element minus half to obtain the depth to the middle of each individual element.

2.3. Numerical Example Results

Using a design example from Reference [1] (See Figure 2), a 20'-0" long by 10" thick ordinary concrete shear wall was designed, and the results were compared to the results obtained using interaction diagrams in the textbook. The wall was to support a combined design axial compression of 1036 kips and a design moment of 15,162 kips. For this example, the number of elements was varied and two cases were used, the first using 24 elements and the second using 100 elements to determine if the spreadsheet was able to achieve convergence. The final steel area was added amongst the elements to obtain the total steel area required and this was compared to the results found in the textbook, which were designed using interaction diagrams. The results comparing the total steel areas from the textbook and the spreadsheet can be found in Table 1. The results showed a small percentage difference between the total steel areas found using the proposed method and the results using the interaction diagram in the textbook.

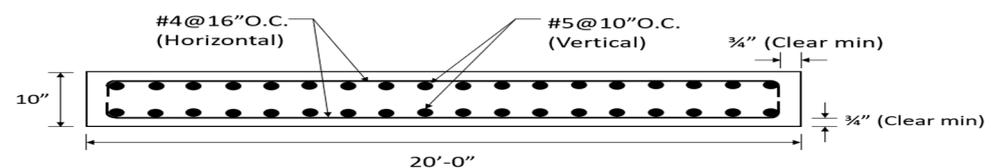

Figure 2. Reinforced concrete shear wall design example [1].

Table 1. Element analysis design results vs. interaction diagram design results.

Method	Total Steel Area (A_s) in ²	Percent Error (%)
Interaction Diagram [1]	14.88	-
Element Analysis ($n = 24$)	14.97	0.605
Element Analysis ($n = 100$)	14.97	0.605

The results showed convergence amongst a variable number of elements as well as showing results within 1% error of those using interaction diagrams. The optimization-based method and Excel spreadsheet allow for ease of use as well as various user inputs based on the desire of the user while providing accurate results to that of shear walls designed using interaction diagrams. More examples will allow for the further contribution and design of the sheet and will be needed to look at the complexity of design that the sheet and Excel solver can handle.

3. Summary and Future Work

In this research, an alternative analysis and design method was developed and applied to reinforced concrete shear walls. A numerical example was studied and the proposed method worked well, and the results were compared with those obtained using the classical methods. The new method using numerical optimization was easy to implement in an Excel spreadsheet, which is useful for practical engineering applications. Future research includes extending the new approach to the design of other concrete structures and members.

Appendix A

Below are the equations used in the design and analysis of the spreadsheet that are inherent equations used in the analysis and design of concrete members, which are not exclusive to the design and use of this sheet [2].

$$\varepsilon_{ti} = [(d_i - c)/c] \varepsilon_{cu} \quad (A1)$$

Equation (A1) shows how the strain for an individual element's steel area is obtained.

$$f_i = f_y \text{ IF } \varepsilon_{ti} > \varepsilon_y \quad (A2)$$

$$f_i = -f_y \text{ IF } \varepsilon_{ti} > -\varepsilon_y \quad (A3)$$

$$f_i = E \times \varepsilon_{ti} \text{ IF } -\varepsilon_y < \varepsilon_{ti} < \varepsilon_y \quad (A4)$$

Equations (A2)–(A4) show how the stress in each element's steel area was obtained based on the corresponding strain of each element.

$$F_i = A_{si}(f_i - 0.85(f_c')) \text{ IF } f_i < 0 \quad (A5)$$

$$F_i = A_{si}f_y \text{ IF } f_i > 0 \quad (A6)$$

Equations (A5) and (A6) show how the force in each element was obtained based on the corresponding steel stress in each element.

$$d_{mi} = d_i - L/2 \quad (A7)$$

Equation (A7) shows how the moment arm for each steel element was obtained.

$$M_n = F_i d_i \quad (A8)$$

Equation (A8) shows how the moment capacity was found for each steel element.

$$\varepsilon_t = [(d_t - c)/c] \varepsilon_{cu} \quad (A9)$$

Equation (A9) shows how the actual strain of the extreme layer of steel was calculated.

$$\Phi = 0.65 + (\varepsilon_t - \varepsilon_y)(0.25/0.003) \quad (A10)$$

Equation (A10) shows how the strength reduction factor was calculated.

$$a = \beta_1 c \quad (A11)$$

Equation (A11) shows how the depth of the concrete compressive stress block was calculated.

$$A_c = ab_w \quad (\text{A12})$$

Equation (A12) shows how the total area of the concrete in compression was calculated.

$$C_c = 0.85(A_c f_c') \quad (\text{A13})$$

Equation (A13) shows how the resultant concrete compression force was calculated.

$$\bar{y} = a/2 \quad (\text{A14})$$

Equation (A14) shows how the centroid of the concrete compressive stress block was calculated.

$$d_c = (L/2 - \bar{y}) \quad (\text{A15})$$

Equation (A15) shows how the depth of the concrete area in compression was calculated.

$$E_{\text{axial}} = C_c - \Sigma(F_i)_I - P_u/\Phi \quad (\text{A16})$$

Equation (A16) shows how the error of axial load equilibrium was determined.

$$\Phi M_n = (C_c (L/2 - \bar{y}) + \Sigma M_{ni})\Phi \quad (\text{A17})$$

Equation (A17) shows how the moment capacity was determined.

$$E_{\text{moment}} = C_c (L/2 - \bar{y}) - \Sigma M_{ni} - M_u/\Phi \quad (\text{A18})$$

Equation (A18) shows how the error of moment equilibrium was determined.
